

Ductile Shape Memory- Amorphous Nanolaminates

Project Manager
Dr. Daniel Söpu

Principal Investigator
Prof. Dr. rer. nat. Karsten Albe

Project Term
2018 - 2019

Project Areas
Materials Science

Clusters
Lichtenberg Cluster Darmstadt

Software
LAMMPS

Institute
Fachgebiet Materialmodellierung

University
Technische Universität Darmstadt

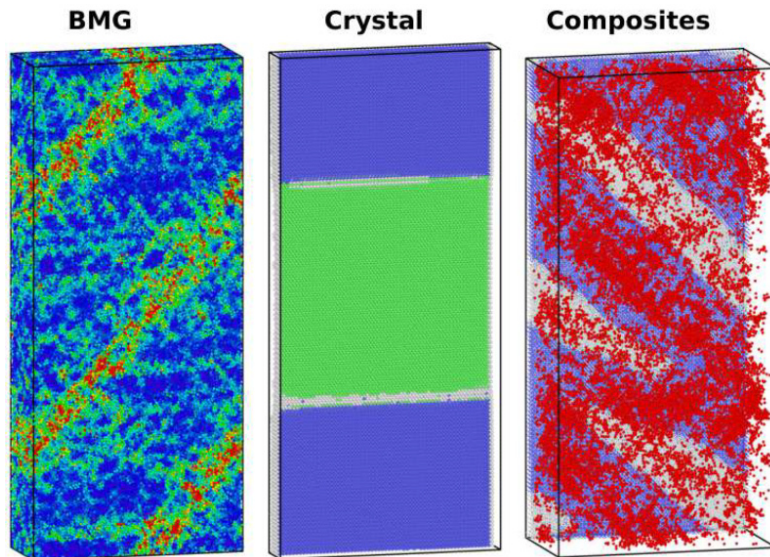

Figure 1: Deformation mechanism of a bulk metallic glass (BMG) (a), a shape memory CuZr crystalline plate (b) and a laminate structure formed by joining both of them (c). The colour scale in (a) indicates the variation of the atomic shear strain from 0.1 to 0.8. The panel (b) shows the results of the CNA in the plastically deformed crystalline plate. To visualize the competing deformation mechanism in the laminate (c) only glassy atoms with a local shear strain higher than 0.2, which indicate STZs, are displayed.

Introduction

We model the deformation behaviour of metallic amorphous/crystalline nanolaminate systems using molecular-dynamics computer simulations. Amorphous-crystalline nanolaminates with shape memory alloys may be a material class which is combining the advantageous properties of metallic glasses with large-strain homogeneous flow at low temperatures and high stresses. Therefore, tailoring the architecture of metallic glass laminates with shape memory phases may allow to develop materials with very large tensile ductility.

Methods

The lack of macroscopic tensile plasticity at room temperature precludes the extensive use of metallic glasses in engineering applications despite their high strength and large elastic limit. A reasonable tensile strain capacity, up to 14 %, is observed in amorphous-crystalline nanolaminates. In order to avoid detrimental run-away shear propagation and ensure shear band arrest, however, the crystalline layers must be sufficiently thick and, thus, occupy an overall volume fraction larger than 80%. For having the full benefit of the superior properties of metallic

glasses; however, one should rather consider nanolaminates, in which the volume fraction of the glassy phase is the dominant one. Metallic glass composites reinforced with shape memory crystals deformed under tension show an enhanced plasticity and also an overall work hardening. Hence, we investigate the deformation behaviour of metallic amorphous/crystalline nanolaminate systems using molecular-dynamics computer simulations. Laminates with different volume fraction and thickness of shape memory phase was constructed.

Results

We found that laminate composites with a low fraction of shape memory layers (below 45 vol. %) experience enhanced tensile ductility and nearly ideal plastic flow behaviour. The exceptional deformability originates from the very complex deformation behaviour, a result of a large number of effects related to the martensitic deformation in the shape memory phase and confinement effects. Our work has provided an atomistic description of the competing and mutual processes of martensitic transformation and shear band formation and shear band dynamics in laminate composites. Therefore, one can predict that amorphous-crystalline nanolaminates with shape memory alloys may be a viable route for developing new materials with large-strain homogeneous flow of metallic glasses at low temperatures and high stresses.
