

# High-Throughput Design of New Perovskite Oxide Antiferroelectric Materials

Project Manager  
Niloofar Hadaeghi

Principal Investigator  
Jun. Prof. Dr. Hongbin Zhang

Project Term  
2020 - 2021

Clusters  
Lichtenberg Cluster Darmstadt

Software  
VASP, ALAMODE

Additional Software  
Abinit

Institute  
Materials Science

University  
Technische Universität Darmstadt

## Introduction

Antiferroelectric (AFE) materials have recently been of a great interest, due to their unique applications in the energy storage devices and non-volatile random access memories. Most of the currently available AFE materials are lead based, which are environmentally harmful. So this unique application of AFE material in one hand and lack of lead-free AFE materials in the other hand, motivated us to study the cubic - AFE phase transition of  $\text{NaNbO}_3$ , as a known AFE material, and the effect of doping on AFE to ferroelectric (FE) phase transition. This better understanding of  $\text{NaNbO}_3$  paves the way to design new lead-free AFE materials.

## Methods

- Cubic - AFE phase of  $\text{NaNbO}_3$

The density functional theory (DFT) calculations was performed to calculate the energy of the interpolated distorted structures. Later on, for Pseudo Jahn-Teller effect (PJTE), we did symmetry analysis and by unfolding the band structures we studied the adiabatic potential energy surface cross section for each mode.

- 0.9375  $\text{NaNbO}_3$  - 0.0625  $\text{SrSnO}_3$  solid solution

Many different Supercells with 80 atoms were generated for both FE and AFE phases to ensure having enough variant Sr-Sn distances. As the AFE-FE phase transition is Displacive, we also considered the corresponding structures.

## Results

- cubic - AFE phase of  $\text{NaNbO}_3$

After relaxation and finding the distortion modes driving the phase transition through cubic paraelectric (PE) to Orthorhombic AFE phase, we found the potential energy surface (PES), as shown in Fig.1.a. Then by fitting the energies to the Hamiltonian model based on Landau theory, we concluded that  $R_5^-$  and  $T_2$  modes (the modes responsible for Oxygen rotations) gain more energy, while  $\Delta_5$  mode (the mode responsible for AFE displacement of Nb and Na2 ions) does not decrease the energy, and it individually increases the energy. Biquadratic couplings showed that there is a strong repulsion between  $R_5^-$  and  $T_2$  modes if they coexist without presence of  $\Delta_5$  mode. The gain of energy by the trilinear term denoted the crucial role of this term, as without such a coupling the AFE phase could not be stabilized.

Then we went one step further, and found the electronic force driving this phase transition by PJTE. The results showed that coupling of  $T_{2u}$  ground state and  $T_{2g}$  excited state, creating  $\Delta_5$  mode, is the electronic source of instability. This shows the overlap of O-2p and Nb-4d orbitals which by increasing the covalency between Nb and O ions, creates Nb displacement as the distortion causing the instability in the high-symmetry cubic phase.

- 0.9375  $\text{NaNbO}_3$  - 0.0625  $\text{SrSnO}_3$  solid solution

In the pristine  $\text{NaNbO}_3$  the energy difference between the AFE and FE phases is 2.3 meV/f.u., whereby the FE phase is more stable. This energy difference is further reduced upon  $\text{Sr}^{2+}$  and  $\text{Sn}^{4+}$  substitution and reaches a value of 1.4 meV/f.u. Interestingly, after this substitution, the AFE phase is more stable. Comparing the energy difference between the corresponding structures, also showed the more stability of the AFE phase over FE phase, by doping, in a good agreement with experiment. Two of the corresponded structures are shown as an instance in Fig.2.
